

Efficient Sorting

4 November 2024

Prof. Dr. Sebastian Wild

Learning Outcomes

Unit 4: Efficient Sorting

- **1.** Know principles and implementation of *mergesort* and *quicksort*.
- **2.** Know properties and *performance characteristics* of mergesort and quicksort.
- 3. Know the comparison model and understand the corresponding *lower bound*.
- **4.** Understand *counting sort* and how it circumvents the comparison lower bound.
- **5.** Know ways how to exploit *presorted* inputs.

Outline

4 Efficient Sorting

- 4.1 Mergesort
- 4.2 Quicksort
- 4.3 Comparison-Based Lower Bound
- 4.4 Integer Sorting
- 4.5 Adaptive Sorting
- 4.6 Python's list sort

Why study sorting?

- fundamental problem of computer science that is still not solved
- building brick of many more advanced algorithms
 - for preprocessing
 - as subroutine
- playground of manageable complexity to practice algorithmic techniques

Here:

- "classic" fast sorting method
- exploit partially sorted inputs
- parallel sorting

Algorithm with optimal #comparisons in worst case?

Part I

The Basics

Rules of the game

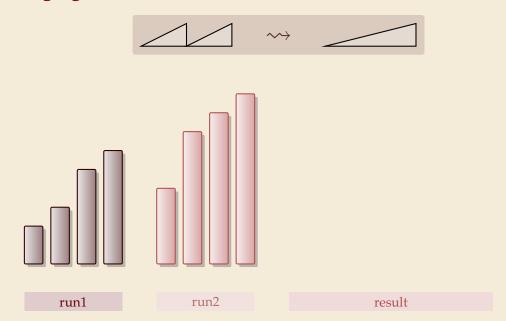

- ► Given:
 - ► array A[0..n) = A[0..n 1] of *n* objects
 - ▶ a total order relation \leq among A[0], ..., A[n-1] (a comparison function)

 Python: elements support <= operator (__le__())

 Java: Comparable class (x.compareTo(y) <= 0)
- ▶ **Goal:** rearrange (i. e., permute) elements within A, so that A is *sorted*, i. e., $A[0] \le A[1] \le \cdots \le A[n-1]$
- ▶ for now: A stored in main memory (internal sorting) single processor (sequential sorting)

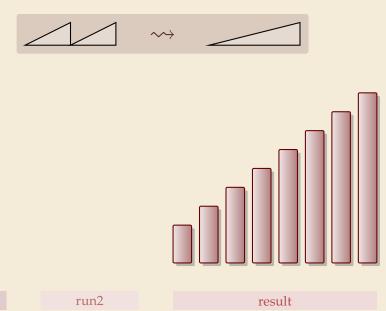

4.1 Mergesort

Merging sorted lists

Merging sorted lists

run1

Mergesort

1 **procedure** mergesort(A[l..r))

- n := r 1
- if n < 1 return $m := l + |\frac{n}{2}|$
- mergesort(A[l..m])
- mergesort(A[m..r))
- merge(A[l..m), A[m..r), buf)7
- copy buf to A[l..r)

- recursive procedure
- merging needs
 - temporary storage *buf* for result (of same size as merged runs)
 - to read and write each element twice (once for merging, once for copying back)

Analysis: count "element visits" (read and/or write)

$$C(n) = \begin{cases} 0 & n \le 1 \\ C(\lfloor n/2 \rfloor) + C(\lceil n/2 \rceil) + 2n & n \ge 2 \end{cases}$$

$$C(n) = \begin{cases} 0 & n \le 1 \\ C(n) = 2n \lg(n) + (2 - \{\lg(n)\} - 2^{1 - \{\lg(n)\}}) 2n \\ \text{with } \{x\} := x - \lfloor x \rfloor \end{cases}$$

Simplification $n = 2^k$ same for best and worst case!

$$\left(\begin{array}{l} \text{precisely(!) solvable } \textit{without } \text{assumption } n = 2^k \colon \\ C(n) = 2n \lg(n) + \left(2 - \{\lg(n)\} - 2^{1 - \{\lg(n)\}}\right) 2n \\ \text{with } \{x\} \coloneqq x - \lfloor x \rfloor \end{array} \right)$$

$$C(2^{k}) = \begin{cases} 0 & k \leq 0 \\ 2 \cdot C(2^{k-1}) + 2 \cdot 2^{k} & k \geq 1 \end{cases} = 2 \cdot 2^{k} + 2^{2} \cdot 2^{k-1} + 2^{3} \cdot 2^{k-2} + \dots + 2^{k} \cdot 2^{1} = 2k \cdot 2^{k}$$

$$C(n) = 2n \lg(n) = \Theta(n \log n)$$
 (arbitrary $n: C(n) \le C(\text{next larger power of 2}) \le 4n \lg(n) + 2n = \Theta(n \log n)$)

Mergesort – Discussion

optimal time complexity of $\Theta(n \log n)$ in the worst case

stable sorting method i. e., retains relative order of equal-key items

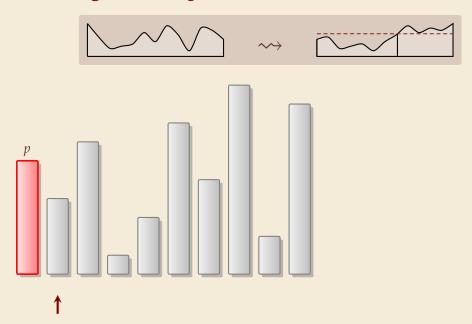

memory access is sequential (scans over arrays)

 \bigcap requires $\Theta(n)$ extra space

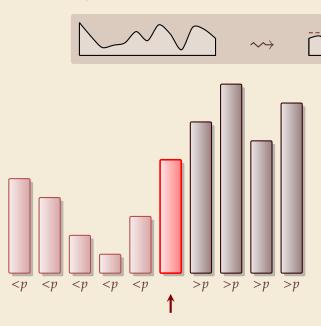

there are in-place merging methods, but they are substantially more complicated and not (widely) used

4.2 Quicksort

Partitioning around a pivot

Partitioning around a pivot

- no extra space needed
- ▶ visits each element once
- ► returns rank/position of pivot

Partitioning – Detailed code

Beware: details easy to get wrong; use this code!

(if you ever have to)

```
procedure partition(A, b)
      // input: array A[0..n), position of pivot b \in [0..n)
      swap(A[0], A[b])
    i := 0, \quad j := n
     while true do
          do i := i + 1 while i < n and A[i] < A[0]
          do j := j - 1 while j \ge 1 and A[j] > A[0]
          if i \ge j then break (goto 11)
          else swap(A[i], A[j])
      end while
10
      swap(A[0], A[i])
11
      return j
12
```

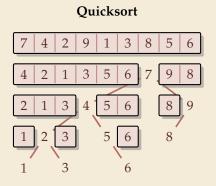

```
Loop invariant (5–10): A \quad p \quad \leq p \quad ? \quad \geq p
```

Quicksort

```
procedure quicksort(A[l..r))
if r - l \le 1 then return
b := choosePivot(A[l..r))
j := partition(A[l..r), b)
quicksort(A[l..j))
quicksort(A[j+1..r))
```

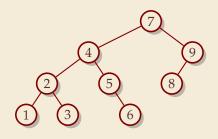

- ► recursive procedure
- choice of pivot can be
 - ▶ fixed position → dangerous!
 - ► random
 - more sophisticated, e.g., median of 3

Quicksort & Binary Search Trees

Binary Search Tree (BST)

- ► recursion tree of quicksort = binary search tree from successive insertion
- ► comparisons in quicksort = comparisons to built BST
- ightharpoonup comparisons in quicksort \approx comparisons to search each element in BST

Quicksort - Worst Case

- ► Problem: BSTs can degenerate
- ightharpoonup Cost to search for k is k-1

$$\rightarrow$$
 Total cost $\sum_{k=1}^{n} (k-1) = \frac{n(n-1)}{2} \sim \frac{1}{2}n^2$

(1) (2) (3) (4) (5) (6)

 \rightsquigarrow quicksort worst-case running time is in $\Theta(n^2)$

terribly slow!

But, we can fix this:

Randomized quicksort:

- choose a random pivot in each step
- → same as randomly shuffling input before sorting

Randomized Quicksort - Analysis

- ightharpoonup C(n) = element visits (as for mergesort)
- \rightarrow quicksort needs $\sim 2 \ln(2) \cdot n \lg n \approx 1.39 n \lg n$ in expectation
- ▶ also: very unlikely to be much worse: e. g., one can prove: $Pr[cost > 10n \lg n] = O(n^{-2.5})$ distribution of costs is "concentrated around mean"
- ▶ intuition: have to be *constantly* unlucky with pivot choice

Ouicksort – Discussion

fastest general-purpose method

 $\Theta(n \log n)$ average case

works *in-place* (no extra space required)

memory access is sequential (scans over arrays)

 $\Theta(n^2)$ worst case (although extremely unlikely)

not a *stable* sorting method

Open problem: Simple algorithm that is fast, stable and in-place.

4.3 Comparison-Based Lower Bound

Lower Bounds

- ▶ **Lower bound:** mathematical proof that *no algorithm* can do better.
 - ▶ very powerful concept: bulletproof impossibility result
 ≈ conservation of energy in physics
 - (unique?) feature of computer science: for many problems, solutions are known that (asymptotically) achieve the lower bound
 - → can speak of "optimal algorithms"
- ▶ To prove a statement about *all algorithms*, we must precisely define what that is!
- ▶ already know one option: the word-RAM model
- ► Here: use a simpler, more restricted model.

The Comparison Model

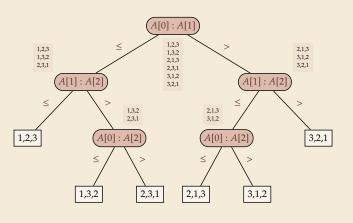

- ▶ In the *comparison model* data can only be accessed in two ways:
 - comparing two elements
 - moving elements around (e.g. copying, swapping)
 - ► Cost: number of comparisons.

That's good! /Keeps algorithms general!

- ► This makes very few assumptions on the kind of objects we are sorting.
- Mergesort and Quicksort work in the comparison model.
- → Every comparison-based sorting algorithm corresponds to a *decision tree*.
 - ▶ only model comparisons → ignore data movement
 - ► nodes = comparisons the algorithm does
 - ► next comparisons can depend on outcomes → different subtrees
 - ► child links = outcomes of comparison
 - ▶ leaf = unique initial input permutation compatible with comparison outcomes

Comparison Lower Bound

Example: Comparison tree for a sorting method for A[0..2]:

- Execution = follow a path in comparison tree.
- → height of comparison tree = worst-case # comparisons
- comparison trees are binary trees
- $\rightsquigarrow \ell \text{ leaves } \rightsquigarrow \text{ height} \ge \lceil \lg(\ell) \rceil$
- ► comparison trees for sorting method must have $\geq n!$ leaves
- \rightarrow height $\geq \lg(n!) \sim n \lg n$ more precisely: $\lg(n!) = n \lg n - \lg(e)n + O(\log n)$
- ▶ Mergesort achieves $\sim n \lg n$ comparisons \rightsquigarrow asymptotically comparison-optimal!
- ▶ Open (theory) problem: Sorting algorithm with $n \lg n \lg(e)n + o(n)$ comparisons?

4.4 Integer Sorting

How to beat a lower bound

- ▶ Does the above lower bound mean, sorting always takes time $\Omega(n \log n)$?
- ▶ **Not necessarily**; only in the *comparison model!*
 - → Lower bounds show where to *change* the model!
- ► Here: sort *n* integers
 - ▶ can do *a lot* with integers: add them up, compute averages, . . . (full power of word-RAM)
 - → we are not working in the comparison model
 - → above lower bound does not apply!
 - but: a priori unclear how much arithmetic helps for sorting ...

Counting sort

- ► Important parameter: size/range of numbers
 - ▶ numbers in range $[0..U) = \{0,..., U-1\}$ typically $U = 2^b \rightsquigarrow b$ -bit binary numbers
- ▶ We can sort n integers in $\Theta(n + U)$ time and $\Theta(U)$ space when $b \leq w$:

Counting sort

```
procedure countingSort(A[0..n))

// A contains integers in range [0..U).

C[0..U) := new integer array, initialized to 0

// Count occurrences

for i := 0, ..., n-1

C[A[i]] := C[A[i]] + 1

i := 0 // Produce sorted list

for k := 0, ... U - 1

for j := 1, ... C[k]

A[i] := k; i := i + 1
```

 count how often each possible value occurs

word size

- produce sorted result directly from counts
- circumvents lower bound by using integers as array index / pointer offset

Can sort n integers in range [0..U) with U = O(n) in time and space $\Theta(n)$.

Integer Sorting – State of the art

- ightharpoonup O(n) time sorting also possible for numbers in range $U = O(n^c)$ for constant c.
 - ightharpoonup radix sort with radix 2^w

► Algorithm theory

- suppose $U = 2^w$, but w can be an arbitrary function of n
- \blacktriangleright how fast can we sort n such w-bit integers on a w-bit word-RAM?
 - for $w = O(\log n)$: linear time (radix/counting sort)
 - for $w = \Omega(\log^{2+\varepsilon} n)$: linear time (signature sort)
 - ▶ for w in between: can do $O(n\sqrt{\lg \lg n})$ (very complicated algorithm) don't know if that is best possible!

* * *

▶ for the rest of this unit: back to the comparisons model!

Part II

Exploiting presortedness

4.5 Adaptive Sorting

Adaptive sorting

- ► Comparison lower bound also holds for the *average case* \rightsquigarrow $\lfloor \lg(n!) \rfloor$ cmps necessary
- ▶ Mergesort and Quicksort from above use $\sim n \lg n$ cmps even in best case

Can we do better if the input is already "almost sorted"?

Scenarios where this may arise naturally:

- ▶ Append new data as it arrives, regularly sort entire list (e.g., log files, database tables)
- Compute summary statistics of time series of measurements that change slowly over time (e. g., weather data)
- ▶ Merging locally sorted data from different servers (e.g., map-reduce frameworks)
- → Ideally, algorithms should *adapt* to input: *the more sorted the input, the faster the algorithm*... but how to do that!?

Warmup: check for sorted inputs

- ► Any method could first check if input already completely in order!
 - Best case becomes $\Theta(n)$ with n-1 comparisons!
 - Usually n-1 extra comparisons and pass over data "wasted"
 - Only catches a single, extremely special case . . .
- ► For divide & conquer algorithms, could check in each recursive call!
 - Potentially exploits partial sortedness!
 - \square usually adds $\Omega(n \log n)$ extra comparisons

For Mergesort, can instead check before merge with a **single** comparison

► If last element of first run ≤ first element of second run, skip merge

How effective is this idea?

```
procedure mergesortCheck(A[l..r))

n := r - l

if n \le 1 return

m := l + \lfloor \frac{n}{2} \rfloor

mergesortCheck(A[l..m))

mergesortCheck(A[m..r))

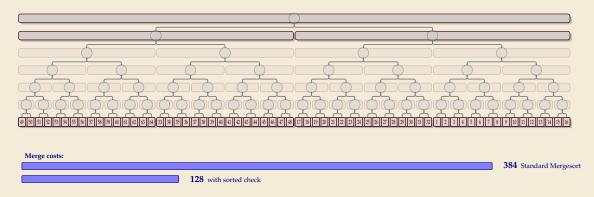

if A[m-1] > A[m]

merge(A[l..m), A[m..r), buf)

copy buf to A[l..r)
```

Mergesort with sorted check – Analysis

- ► Simplified cost measure: *merge cost* = size of output of merges
 - \approx number of comparisons
 - \approx number of memory transfers / cache misses
- **Example** input: n = 64 numbers in sorted *runs* of 16 numbers each:

Sorted check can help a lot!

Alignment issues

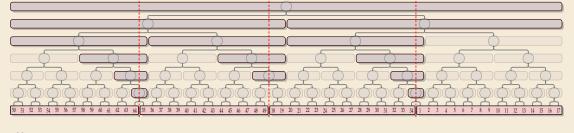

- ▶ In previous example, each run of length ℓ saved us $\ell \lg(\ell)$ in merge cost.
 - = exactly the cost of *creating* this run in mergesort had it not already existed

best savings we can hope for!

Are overall merge costs
$$\mathcal{H}(\ell_1, \dots, \ell_r) := \underbrace{n \lg(n)}_{\text{mergesort}} - \underbrace{\sum_{i=1}^r \ell_i \lg(\ell_i)}_{\ell_i}$$
?

Unfortunately, not quite:

savings from runs

Merge costs:

384 Standard Mergesort

216 with sorted check

127.8 H(15, 15, 17, 17)

Bottom-Up Mergesort

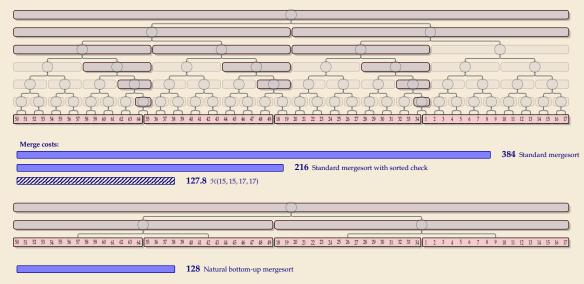

► Can we do better by explicitly detecting runs?

```
procedure bottomUpMergesort(A[0..n))
       Q := new Queue // runs to merge
       // Phase 1: Enqueue singleton runs
       for i = 0, ..., n - 1 do
            Q.enqueue((i, i + 1))
5
       // Phase 2: Merge runs level—wise
       while Q.size() \ge 2
7
            Q' := \text{new Queue}
            while Q.size() \ge 2
                (i_1, j_1) := Q.dequeue()
10
                (i_2, j_2) := Q.dequeue()
11
                merge(A[i_1..j_1), A[i_2..j_2), buf)
12
                copy buf to A[i_1..i_2)
13
                Q'.enqueue((i_1, j_2))
14
            if \neg Q.isEmpty() // lonely run
15
                Q'.enqueue(Q.dequeue())
16
            Q := Q'
17
```

```
1 procedure naturalMergesort(A[0..n))
                                        find run A[i..i]
       Q := \text{new Queue}; i := 0
                                        starting at i
       while i < n
            i := i + 1
            while A[j] \ge A[j-1] do j := j+1
            Q.enqueue((i, j)); i := j
        while Q.size() \ge 2
7
            Q' := \text{new Queue}
            while Q.size() \ge 2
                 (i_1, j_1) := Q.dequeue()
10
                 (i_2, j_2) := Q.dequeue()
11
                 merge(A[i_1..i_1), A[i_2..i_2), buf)
12
                 copy buf to A[i_1..i_2)
13
                 Q'.enqueue((i_1, j_2))
14
            if \neg Q.isEmpty() // lonely run
15
16
17
```

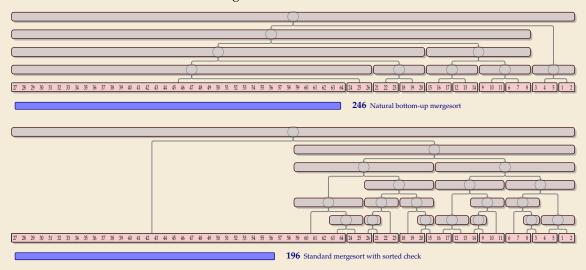

Natural Bottom-Up Mergesort – Analysis

▶ Works well runs of roughly equal size, regardless of alignment . . .

Natural Bottom-Up Mergesort – Analysis [2]

▶ ... but less so for uneven run lengths

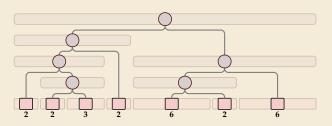

... can't we have both at the same time?!

Good merge orders

Let's take a step back and breathe.

- Conceptually, there are two tasks:
 - **1.** Detect and use existing runs in the input $\rightarrow \ell_1, \dots, \ell_r$
 - Determine a favorable *order of merges* of runs ("automatic" in top-down mergesort)

Merge cost = total area of (

= total length of paths to all array entries

$$= \sum_{w \text{ leaf}} weight(w) \cdot depth(w)$$

with known algorithms optimal merge tree = optimal *binary search tree* for leaf weights ℓ_1, \ldots, ℓ_r (optimal expected search cost)

well-understood problem

Nearly-Optimal Mergesort

Nearly-Optimal Mergesorts: Fast, Practical Sorting Methods That Optimally Adapt to Existing Runs

J. Ian Munro

- Abstract

We present two stable mergesort variants, "peeksort" and "powersort", that exploit existing runs and find nearly-optimal merging orders with negligible overhead. Previous methods either require substantial effort for determining the merging order (Takaoka 2009: Barbay & Navarro 2013) or do not have an optimal worst-case guarantee (Peters 2002; Auger, Nicaud & Pivoteau 2015; Buss & Know 2018). We demonstrate that our methods are commetitive in terms of running time with state-of-the-art implementations of stable sorting methods.

1 Introduction

Sorting is a fundamental building block for numerous tasks and ubiquitous in both the theory and practice of computing. While practical and theoretically (close-to) optimal comparison-based sorting methods are known, instance-optimal sorting, i.e., methods that adept to the actual input and exploit specific structural properties if present, is still an area of active research. We survey some recent developments in Section 1.1

Many different structural properties have been investigated in theory. Two of them have also found wide adoption in practice, e.g., in Oracle's Java runtime library: adapting to the presence of duplicate keys and using existing sorted segments, called runs. The former is achieved by a so-called fat-pivot partitioning variant of quicksort [8], which is also used in the OpenBSD implementation of quort from the C standard library. It is an wastable sorting method, though, i.e., the relative order of elements with could keys might be destroyed in the process. It is hence used in Java solely for primitive-type arrays

Leibniz International Proceedings in Informatic Daystuhi Publishing Germany
UPIG Schloss Daystuhi - Leibniz-Zontrum für Informatik. Daystuhi Publishing. Germany

- ▶ In 2018, with Ian Munro, I combined research on nearly-optimal BSTs with mergesort
- → 2 new algorithms: Peeksort and Powersort
 - both adapt provably optimal to existing runs even in worst case: $mergecost \leq \mathcal{H}(\ell_1, \dots, \ell_r) + 2n$
 - both are lightweight extensions of existing methods with negligible overhead
 - both fast in practice

Peeksort

- ▶ based on top-down mergesort
- "peek" at middle of array& find closest run boundary
- → split there and recurse
 (instead of at midpoint)

- ► can avoid scanning runs repeatedly:
 - ► find full run straddling midpoint
 - remember length of known runs at boundaries

with clever recursion, scan each run only once.

Peeksort - Code

```
1 procedure peeksort(A[\ell..r), \Delta_{\ell}, \Delta_{r})
                 if r - \ell < 1 then return
                if \ell + \Delta_{\ell} == r \vee \ell == r + \Delta_r then return
               m := \ell + \lfloor (r - \ell)/2 \rfloor
5 i := \begin{cases} \ell + \Delta_{\ell} & \text{if } \ell + \Delta_{\ell} \ge m \\ \text{extendRunLeft}(A, m) & \text{else} \end{cases}
6 j := \begin{cases} r + \Delta_{r} \le m & \text{if } r + \Delta_{r} \le m \le m \\ \text{extendRunRight}(A, m) & \text{else} \end{cases}
g := \begin{cases} i & \text{if } m - i < j - m \\ j & \text{else} \end{cases}
\delta \Delta_g := \begin{cases} j - i & \text{if } m - i < j - m \\ i - j & \text{else} \end{cases}
                peeksort(A[\ell..g), \Delta_{\ell}, \Delta_{g})
                 peeksort(A[g,r), \Delta_g, \Delta_r)
 10
                 merge(A[\ell,g),A[g..r),buf)
11
                 copy buf to A[\ell..r)
12
```

► Parameters:

- initial call: peeksort(A[0..n), Δ_0 , Δ_n) with $\Delta_0 = \text{extendRunRight}(A, 0)$ $\Delta_n = n - \text{extendRunLeft}(A, n)$
- helper procedure

```
procedure extendRunRight(A[0..n), i)

j := i + 1

while j < n \land A[j - 1] \le A[j]

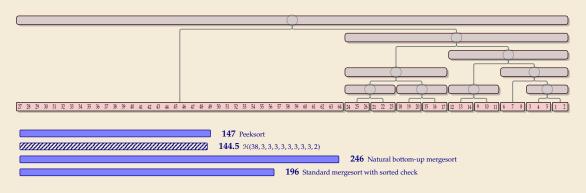

j := j + 1

return j
```

(extendRunLeft similar)

Peeksort – Analysis

► Consider tricky input from before again:

- ▶ One can prove: Mergecost always $\leq \Re(\ell_1, \dots, \ell_r) + 2n$
- → We can have the best of both worlds!

4.6 Python's list sort

Sorting in Python

- ► CPython
 - Python is only a specification of a programming language
 - ► The Python Foundation maintains *CPython* as the official reference implementation of the Python programming language
 - If you don't specifically install something else, python will be CPython
- part of Python are list.sort resp. sorted built-in functions
 - ▶ implemented in C
 - use *Timsort*, custom Mergesort variant by Tim Peters

Sept 2021: **Python uses** *Powersort*! since CPython 3.11 and PyPy 7.3.6

Timsort (original version)

```
procedure Timsort(A[0..n))

i := 0; runs := new Stack()

while i < n

j := ExtendRunRight(A, i)

runs.push(i, j); i := j

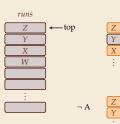

while rule A/B/C/D applicable

merge corresponding runs

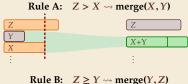

while runs.size() \geq 2

merge topmost 2 runs
```

- above shows the core algorithm; many more algorithm engineering tricks
- Advantages:
 - profits from existing runs
 - locality of reference for merges
- ► **But:** *not* optimally adaptive! (next slide)
 Reason: Rules A–D (Why exactly these?!)

 $\neg A, \neg B, \neg C$

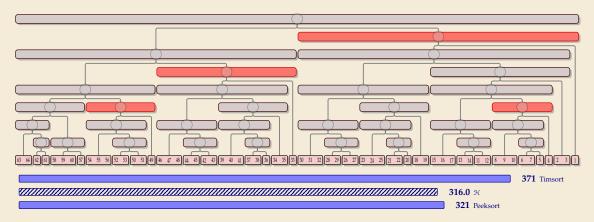

Rule C: $Y + Z \ge X \leadsto merge(Y, Z)$

Timsort bad case

▶ On certain inputs, Timsort's merge rules don't work well:

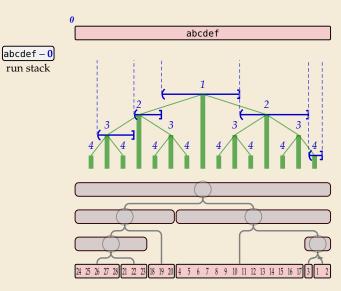

- As n increases, Timsort's cost approach $1.5 \cdot \mathcal{H}$, i. e., 50% more merge costs than necessary
 - intuitive problem: regularly very unbalanced merges

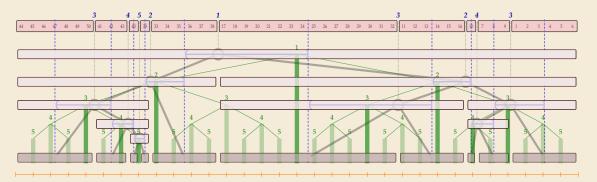

Powersort

→ Timsort's *merge rules* aren't great, but overall algorithm has appeal . . . can we keep that?

```
1 procedure Powersort(A[0..n])
       i := 0; runs := new Stack()
       j := \text{ExtendRunRight}(A, i)
       runs.push((i,j),0); i := j
       while i < n
           j := \text{ExtendRunRight}(A, i)
           p := power(runs.top(), (i, j), n)
           while p \le runs.top().power
               merge topmost 2 runs
9
           runs.push((i, j), p); i := j
10
       while runs.size() \ge 2
           merge topmost 2 runs
12
```

Powersort – Run-Boundary Powers

- ► (virtual) perfect balanced binary tree
- ▶ midpoint intervals "snap" to closest virtual tree node
 - → assigns each run boundary a depth = its *power*
- \leadsto merge tree follows virtual tree

Powersort – Run-Boundary Powers are Local

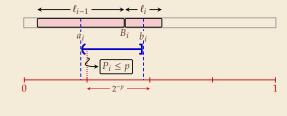

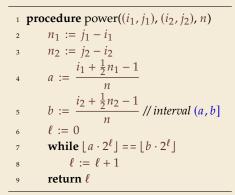

Computation of powers only depends on two adjacent runs.

Powersort – Computing powers

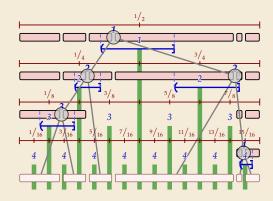

- Computing the power of (run boundary between) two runs
 - ► ← = normalized midpoint interval
 - ▶ power = min ℓ s.t. \leftarrow contains $c \cdot 2^{-\ell}$

 \blacktriangleright with bitwise trickery O(1) time possible

Powersort – Discussion

Retains all advantages of Timsort

- good locality in memory accesses
- no recursion
- all the tricks in Timsort

optimally adapts to existing runs

minimal overhead for finding merge order
